Predicting the chances of recovery of consciousness and communication in patients who survive their coma but transit in a vegetative state or minimally conscious state (MCS) remains a major challenge for their medical caregivers. Very few studies have examined the slow neuronal changes underlying functional recovery of consciousness from severe chronic brain damage. A case study in this issue of the JCI reports an extraordinary recovery of functional verbal communication and motor function in a patient who remained in MCS for 19 years (see the related article beginning on page 2005). Diffusion tensor MRI showed increased fractional anisotropy (assumed to reflect myelinated fiber density) in posteromedial cortices, encompassing cuneus and precuneus. These same areas showed increased glucose metabolism as studied by PET scanning, likely reflecting the neuronal regrowth paralleling the patient’s clinical recovery. This case shows that old dogmas need to be oppugned, as recovery with meaningful reduction in disability continued in this case for nearly 2 decades after extremely severe traumatic brain injury.

Forty years ago, Plum and Posner published the first edition of their landmark book, *The diagnosis of stupor and coma* (1). Since then, clinical research efforts in the field of acute brain damage and coma have increased nearly exponentially. Comatose patients who survive thanks to ever-improving intensive care medicine classically begin to awaken and recover consciousness within some days to weeks or will enter a vegetative state (VS). The clinical criteria of this diagnostic entity of “wakefulness without awareness” were first set out by Jennet and Plum in their 1972 milestone paper (2). The VS may be a transitional state on the route to further recovery or, unlike coma, which virtually never becomes chronic, the VS may progress to a long-standing, sometimes irreversible condition. Permanent VS, a prognostic term to be used with great caution, implies the prediction that the patient will not recover. It was introduced by the Multi-Society Task Force on PVS (persistent vegetative state) to denote irreversibility of the condition after 3 months following a nontraumatic brain injury.

![Figure 1](image)

**Figure 1**
PET studies show that in the rare patients who recover consciousness after being in a chronic VS, glucose metabolism is partially restored in discrete cortical regions. (A) The most significant restoration of glucose metabolism occurs in the posteromedial cortices (shown in white on a medial view of a 3D-rendered MRI). The arrows represent the corticocortical and corticothalamo-cortical functional disconnections observed in vegetative patients. MF, mesofrontal cortex; P, precuneus; T, thalamus (nonspecific nuclei). (B) Metabolism in this area is significantly impaired during the VS (black) but resumes near-normal activity after recovery of consciousness (REC; gray). Normal resting metabolic rates of glucose as measured in healthy controls are shown for comparison (CON; white). In this issue of the JCI, Voss and coworkers report on their observation of intracortical connectivity changes in the same area of the brain, as assessed by diffusion tensor MRI, in an exceptional patient who emerged after spending 19 years in an MCS (12). This residual cerebral plasticity in chronic disorders of consciousness has been largely overlooked by the medical community and deserves further study to expose its underlying cellular mechanisms. Figure and data adapted with permission from the *Journal of Neurology, Neurosurgery, and Psychiatry* (22).

**Nonstandard abbreviations used:** MCS, minimally conscious state; VS, vegetative state.

Understanding “miracle” recoveries from “coma”

“The brain is a mystery and even more so in these states,” says the nurse caring for a beautiful dancer in a VS in Pedro Almodóvar’s Academy Award–winning motion picture Habla con ella (Talk to her). Chronic coma (which is much more rare in clinical practice than it is in Hollywood scenarios) and VS or MCS, especially unexpected recovery from these, have always incited the media and public. Several reports in the popular media have described dramatic recovery from “coma.” In nearly all reports, recovery of consciousness and function occurred in VS or MCS patients and, in most individuals, recovery occurred within the time frames mentioned above. Incredible cases of recovery reported in the popular media or even the medical literature are often very poorly documented—the nature of the patients’ neurologic condition is imprecise, or the timing of the entry into the VS or MCS is extremely atypical (11). In this issue of the JCI, Voss and colleagues present the extraordinary case of recovery from MCS 19 years after traumatic brain injury of a 39-year-old patient (12). The authors have taken the initiative to carefully check this individual’s medical history and personally examine this “miracle recovery from coma” case, which was widely covered in the popular media (e.g., see ref. 13). The authors have complemented extensive neuropsychological testing with state-of-the-art structural and functional neuroimaging techniques. Changes in the patient’s brain structure and function were compared with measurements obtained in healthy controls and in another MCS patient, the latter not showing recovery after 6 years. Very few neuroimaging studies have tackled the issue of late recovery of consciousness in severe brain damage. The most remarkable finding in the Voss et al. study (12) was the MRI assessment of transiently increased fractional anisotropy and directionality in the posterior midline cortices (encompassing the cuneus and precuneus), interpreted as increased myelinated fiber densities and novel corticocortical sprouting, paralleling the emergence of the patient from MCS. The same area of the patient’s brain also showed amplified metabolic changes underlying neuronal metabolic changes (Figure 1), followed by a wide network of frontoparietal associative cortices. In some VS or MCS patients, the disorder of consciousness seems due to a functional “disconnection syndrome” (16, 24). Long-range cortico-cortical (between midline-posterior and latero-frontal areas) and corticothalamic (between midline-posterior cortices and nonspecific thalamic nuclei) disconnections could be identified in a cohort of VS patients, and the rare cases that recovered showed a partial functional restoration of these connections (22, 25). The fiber-tracking MRI studies reported by Voss et al. in this issue of the JCI (12) offer indications as to the cellular mechanisms underlying this functional normalization. Their quantification of white matter reorganization shows long-distance rewiring in posterior medial cortices, possibly reflecting axonal sprouting or neurite outgrowth, maybe even related to neurogenesis (known to occur primarily in associative cortices in normal primates) (26).

Severe brain damage represents an immense medical, social, and economic problem that warrants further research. Chronically unconscious or minimally conscious patients present unique problems for diagnosis, prognosis, treatment, and everyday management. They are vulnerable to being denied potentially life-saving therapy if clinical research remains solely focused on the acute stage of the disease. Current functional neuroimaging techniques can prospectively quantify residual neuronal plasticity and the challenging process of recovery. The findings of Voss and coworkers (12) will increase our understanding of severely brain-damaged patients and their “miracle” recovery of consciousness.

Searching for the neural correlate of consciousness

Our center had the opportunity to study neuronal metabolic changes underlying recovery from VS. To date, of 60 patients studied using fluorodeoxyglucose PET, 7 patients recovered consciousness and could be rescanned. In these patients, we localized the brain areas where metabolism was most impaired during the VS and returned to near-normal values after recovery (22, 23). Such analyses identified the precuneus (Brodmann areas 7 and 31) as the area showing the largest recovery-related metabolic changes (Figure 1), followed by a wide network of frontoparietal associative cortices. In some VS or MCS patients, the disorder of consciousness seems due to a functional “disconnection syndrome” (16, 24). Long-range cortico-cortical (between midline-posterior and latero-frontal areas) and corticothalamic (between midline-posterior cortices and nonspecific thalamic nuclei) disconnections could be identified in a cohort of VS patients, and the rare cases that recovered showed a partial functional restoration of these connections (22, 25). The fiber-tracking MRI studies reported by Voss et al. in this issue of the JCI (12) offer indications as to the cellular mechanisms underlying this functional normalization. Their quantification of white matter reorganization shows long-distance rewiring in posterior medial cortices, possibly reflecting axonal sprouting or neurite outgrowth, maybe even related to neurogenesis (known to occur primarily in associative cortices in normal primates) (26).

Severe brain damage represents an immense medical, social, and economic problem that warrants further research. Chronically unconscious or minimally conscious patients present unique problems for diagnosis, prognosis, treatment, and everyday management. They are vulnerable to being denied potentially life-saving therapy if clinical research remains solely focused on the acute stage of the disease.
